

Early Journal Content on JSTOR, Free to Anyone in the World

This article is one of nearly 500,000 scholarly works digitized and made freely available to everyone in the world by JSTOR.

Known as the Early Journal Content, this set of works include research articles, news, letters, and other writings published in more than 200 of the oldest leading academic journals. The works date from the mid-seventeenth to the early twentieth centuries.

We encourage people to read and share the Early Journal Content openly and to tell others that this resource exists. People may post this content online or redistribute in any way for non-commercial purposes.

Read more about Early Journal Content at <http://about.jstor.org/participate-jstor/individuals/early-journal-content>.

JSTOR is a digital library of academic journals, books, and primary source objects. JSTOR helps people discover, use, and build upon a wide range of content through a powerful research and teaching platform, and preserves this content for future generations. JSTOR is part of ITHAKA, a not-for-profit organization that also includes Ithaka S+R and Portico. For more information about JSTOR, please contact support@jstor.org.

CURRENT LITERATURE

NOTES FOR STUDENTS

Mucor and Chaetocladium.—BURGEFF¹ has given an interesting account of the relations between the parasite *Chaetocladium* and the host *Mucor*. The *Chaetocladium* investigated reacts physiologically like *C. Fresenianum*, but morphologically more like *C. Brefeldi*, although its spores are larger than in the latter species. The *Mucor* host was a variety of *Mucor mucedo* which BURGEFF describes as *Mucor mucedo dependens*.

The course of infection was followed in both fixed and living condition. Fortunately the plasma of the parasite stains more deeply than that of the host, so that host and parasite can be distinguished in sectioned material. When growing together the filaments of the *Mucor* host are attracted by those of *Chaetocladium*. Filaments of the parasite apparently are not attracted by those of the host until they are within a very short distance of each other. Contact of the two kinds of filaments is a stimulus which causes a slight thickening of the tip of the *Chaetocladium* hypha, inhibits its growth in length, and finally causes the formation of a cross wall cutting off the terminal portion of the filament of the parasite, which becomes the gall cell. The adjacent walls of the host and parasite dissolve, and plasma and nuclei of the host enter the gall cell, which at once swells and branches. In the gall cell the nuclei of the host are arranged peripherally and undergo division, while those of the parasite are centrally located and apparently do not divide. The gall cell is termed heterocaryotic (or a mixochimaera), since it contains two kinds of nuclei in contrast with the homocaryotic hyphae of the host and of the parasite. It is in open communication with the host hypha, but separated from the parasite by a membrane. Some of the branches from the primary gall are heterocaryotic and some homocaryotic, containing only *Mucor* nuclei. These latter branches form secondary galls in contact with pure *Chaetocladium* filaments. Apparently gall branches never contain only *Chaetocladium* nuclei, perhaps because the latter do not divide when in association with the host plasma. Branches of *Chaetocladium* from below the gall intermingle with those of the latter, thus increasing the area of contact between the gall and parasite. Apparently it is only at contact surfaces between the heterocaryotic gall and the *Chaetocladium* hyphae that diffusion to the advantage of the parasite can take place. At any rate, after contact of *Chaetocladium*

¹ BURGEFF, H., Über den Parasitismus des *Chaetocladium* und die heterocaryotische Natur der von ihm auf Mucorineen erzeugten Gallen. Zeitsch. Botanik 12: 1-35. figs. 36. 1920.

filaments with these gall cells the parasite grows out into fruiting branches. Single nuclei enter the single-spored sporangium and later divide twice, producing the four nuclei of each spore (rarely two or more than four).

The association of the plasma of host and parasite in a mixochimaera is supposed to render the protoplasmic membranes of the host permeable to diffusion of the material necessary to the normal growth of the parasite. The galls are also supposed to serve as a means of bringing about a branching of the host hypha in places such as old sporangiophores, where the ability to branch has been lost.

In seeking for a possible origin of the "sikyotic" parasitism (from *σικυα* = a cupping-glass) of *Chaetocladium*, BURGEFF discusses other cases of fusions in the fungi. In the anastomoses found in *Mortierella*, *Syncephalis*, *Ascomycetes*, and *Basidiomycetes*, a cross wall, if formed, is produced after the fusion, as shown by KNIPEP, but in this case the process is connected with the distribution of nuclei in a diploid mycelium. Failing to find an analogy with vegetative processes, BURGEFF suggests that the curious type of parasitism which he has studied may have originated by way of sexual fusions; and in support of this suggestion points out the similarities between the processes involved in conjugation in the *Mucors* and those in the formation of his sikyotic galls in *Chaetocladium*. The suggestion is believed to need strengthening by tests with plus and minus races of host and parasite.—A. F. BLAKESLEE.

Calcium.—SHEDD² has found that the procedure which has been adopted by the Association of Official Agricultural Chemists for determination of calcium in soil solution does not give accurate results, due to the occlusion of calcium on the iron and aluminum precipitate that goes through the filter. He has evolved a new method which is simpler and avoids the errors of the present methods. The following findings for the Kentucky soils are of great interest. Cultivation has caused a considerable loss of calcium from these soils. The best types of these soils have the highest calcium content, and the poorest have the lowest. "Many samples have been found to be so low in calcium that their deficiency in this constituent requires consideration as well as their low phosphorus and nitrogen supply. The application of a ton of limestone or of rock phosphate per acre to such soils frequently adds more calcium than is already present. There is no doubt that, in such cases, these materials, or even moderate applications of some commercial fertilizers, are beneficial because of the plant food (calcium) they supply in addition to other good effects they may accomplish."

NELLER,³ working on limed and unlimed plots of the New Jersey Experiment Station, finds that the oxidizing power of the limed plots is approxi-
